pratik.niroula@mnsu.edu

Abstract*—Autonomous physical systems increasingly rely on deep learning and complex predictive models for closed-loop control. However, when deployed in real-world environments, sensing pipelines suffer non-stationary degradation: packet loss, latency jitter, calibration drift, and sensor occlusion. In such regimes, conventional safety controllers create an *Observation–Action Safety Gap (OASG)*, certifying actions that appear safe on degraded telemetry while the true physical state violates dynamic safety boundaries. This paper introduces ORIUS + K-Bound, a foundational framework for certified action release under observation degradation. We formalize physical safety as a viability invariance problem and establish eight core theorems (Theorems A–H): (1) *Viability-Preserving Release Feasibility*; (2) *Minimax Information Lower Bound*; (3) *Trajectory Safety Achievability*; (4) *Safety–Utility Regret Bounds*; (5) *Universal Transferability*; (6) *Terminal Safe-Stop Viability (TV-SSK) under Unbounded Blackouts*; (7) *Anytime-Valid Betting Martingale Shift Detection & Byzantine Resilience*; and (8) *Cyber-Physical & Financial Safe-Liquidation Isomorphism*. We mechanize these results in the Lean 4 proof assistant (`formal/Orius/TheoremsFGH.lean`) with zero unverified axioms or `sorry` gaps. Across seven real-data physical and financial domains ($224,000$ total simulation steps), 100,000-agent adversarial swarms, and closed-loop mobile robot (200 episodes) and battery BMS bench (4,800 steps) hardware-in-the-loop verification, ORIUS+K-Bound achieves a 0.000% true trajectory violation rate with sub-microsecond native C++17 execution latency ($0.0056\,\mu$s median, 177.9 MHz).

***Index Terms*—Physical AI, Certified Control, Safety Filter, Partial Observability, Conformal Prediction, Viability Theory, Formal Verification.**

I. Introduction

As physical artificial intelligence (Physical AI) systems—such as autonomous vehicles, smart grid power inverters, robotic manipulators, and grid-scale battery storage—transition from isolated simulators to open-world deployment, safety certification becomes the primary bottleneck. A prevalent assumption in modern predictive safety filters and control barrier functions (CBFs) is either full state observation or stationary Gaussian estimation error with bounded covariance [1], [2].

In reality, real-world physical telecommunication and perception pipelines frequently violate these assumptions. Telemetry dropouts, sensor degradation, clock jitter, and adversarial disturbances degrade telemetry non-stationarily [3], [4]. When safety filters evaluate barrier conditions or constraint satisfaction solely on degraded observations, they suffer from what we designate the **Observation–Action Safety Gap (OASG)**: the controller perceives a positive safety margin, yet the underlying unobserved true physical state penetrates the safety boundary.

To resolve this challenge, we organize the ORIUS framework around one foundational thesis:

> *An autonomous physical system should release an action only when its available information, uncertainty model, and verified control authority support the required safety guarantee. ORIUS characterizes when such release is possible, when it is impossible, and how to enforce it efficiently across heterogeneous physical systems.*

Rather than framing safety filtering as an empirical optimization heuristic, ORIUS addresses four fundamental questions:

1) **Knowability:** When can a physical system distinguish safe states from hazard states under degraded observation?
2) **Possibility:** Under what observation degradation and actuator authority does any acceptably safe action exist?
3) **Achievability:** Can an online algorithm compute and release such an action with a provable trajectory-level safety guarantee?
4) **Usefulness:** Can certified action release be achieved without unnecessarily forfeiting task performance or exceeding real-time computational deadlines?

A. Summary of Contributions

- **Foundational Theoretical Characterization (Theorems A–H):** We establish recursive viability under action release (Theorem A), derive the minimax lower bound proving the necessity of fallback (Theorem B), prove non-asymptotic trajectory safety achievability (Theorem C), characterize the Pareto regret frontier (Theorem D), formulate universal plant transferability (Theorem E), and extend to unbounded blackouts, martingale shift immunity [5], and financial market impact [8] via Theorems F–H.
- **Formal Machine Assurance in Lean 4:** We mechanize the core mathematical theorems in Lean 4 (`formal/Orius/TheoremsAE.lean` and `formal/Orius/TheoremsFGH.lean`), eliminating circular definitions and tautological proofs.
- **Heterogeneous Physical & Financial Adapters:** We implement concrete, fully auditable domain adapters

across battery storage (BESS), power grid inverters, ROS 2 mobile robotics, autonomous driving, ICU healthcare, aerospace, industrial process control, and L2 financial markets.

- **Empirical, Swarm, and Hardware-in-the-Loop Validation:** Across $224,000$ 7-domain evaluation steps, 100k-agent swarms, and closed-loop mobile robot (Suite A) and battery bench (Suite B) verification, ORIUS+K-Bound eliminates 100% of true-state safety violations (TSVR $= 0.000\%$) with C++17 latencies down to $0.0056\,\mu$s.

II. Problem Formulation & Physical Invariants

Consider a discrete-time physical plant governed by nonlinear dynamics:

$$x_{t+1} = f(x_t, u_t) + w_t, \quad x_t \in \mathcal{X} \subseteq \mathbb{R}^n,\ u_t \in \mathcal{U} \subseteq \mathbb{R}^m, \tag{1}$$

where $w_t \in \mathcal{W} \subset \mathbb{R}^n$ represents bounded physical disturbance ($\|w_t\|_\infty \leq \bar{w}$). The system possesses an admissibility domain $\mathcal{S}_d \subset \mathcal{X}$.

Definition 1 (Viable Safety Domain)**.** *A set $\mathcal{V} \subseteq \mathcal{S}_d$ is a* viable safety domain *if for every state $x \in \mathcal{V}$, there exists at least one admissible control action $u \in \mathcal{U}$ such that for all admissible disturbances $w \in \mathcal{W}$, the successor state remains within $\mathcal{V}$:*

$$\forall x \in \mathcal{V}, \quad \exists u \in \mathcal{U} : \quad f(x,u) + w \in \mathcal{V}, \quad \forall w \in \mathcal{W}. \tag{2}$$

A. Degraded Observation Model

The true state x_t is hidden. The controller receives degraded telemetry y_t:

$$y_t = g(x_t, \nu_t, d_t), \quad d_t \in \{0,1\}, \tag{3}$$

where ν_t represents sensor noise and $d_t = 1$ denotes telemetry packet loss ($y_t = \emptyset$). An Observation Quality Estimator (OQE) computes a health metric $w_t \in [0,1]$ based on packet arrival timestamps, innovation covariance, and physical plausibility bounds. The runtime shield constructs an uncertainty set $\mathcal{X}_t(\alpha_t)$ via conformalized quantile calibration [3], [4] such that:

$$\Pr(x_t \in \mathcal{X}_t(\alpha_t)) \geq 1 - \alpha_t. \tag{4}$$

III. Theoretical Foundations

A. Theorem A: Viability-Preserving Release Feasibility

Theorem 1 (Recursive Viability Invariance)**.** *Let $\mathcal{V} \subseteq \mathcal{S}_d$ be a non-empty viable domain with safe fallback action $u_{\mathrm{fb}} \in \mathcal{U}$ satisfying $\forall x \in \mathcal{V}, \forall w \in \mathcal{W} : f(x, u_{\mathrm{fb}}) + w \in \mathcal{V}$. For any non-empty uncertainty set $\mathcal{X}_t \subseteq \mathcal{V}$, define the certified action release set:*

$$\mathcal{U}_{\mathrm{safe}}(\mathcal{X}_t) \triangleq \{u \in \mathcal{U} \mid \forall x \in \mathcal{X}_t,\, \forall w \in \mathcal{W} : f(x,u) + w \in \mathcal{V}\}. \tag{5}$$

Then:

1) *$\mathcal{U}_{\mathrm{safe}}(\mathcal{X}_t)$ is guaranteed non-empty ($u_{\mathrm{fb}} \in \mathcal{U}_{\mathrm{safe}}(\mathcal{X}_t)$).*
2) *Any released action $u_t \in \mathcal{U}_{\mathrm{safe}}(\mathcal{X}_t)$ guarantees $x_{t+1} \in \mathcal{V} \subseteq \mathcal{S}_d$ for all true states $x_t \in \mathcal{X}_t$.*

B. Theorem B: Minimax Lower Bound on Mandatory Fallback

Theorem 2 (Information Necessity)**.** *Let $x^{(1)}, x^{(2)} \in \mathcal{V}$ be two physical states indistinguishable under observation y_t ($\Pr(y_t \mid x^{(1)}) = \Pr(y_t \mid x^{(2)}) > 0$). If their respective admissible viable control sets are disjoint:*

$$\mathcal{U}_{\mathrm{viable}}(x^{(1)}) \cap \mathcal{U}_{\mathrm{viable}}(x^{(2)}) = \emptyset, \tag{6}$$

then no single released action $u \in \mathcal{U}$ can guarantee safety for both states. Any controller releasing an action must incur a Bayes risk lower bound:

$$\mathcal{R}^* \geq \min(\pi(x^{(1)}), \pi(x^{(2)})), \tag{7}$$

proving that fallback invocation (or active probing) is mathematically mandatory.

C. Theorem C: Trajectory Safety Achievability Bound

Theorem 3 (Non-Asymptotic Trajectory Safety)**.** *Suppose the plant operates over horizon T. Let uncertainty sets $\mathcal{X}_t(\alpha_t)$ satisfy marginal conformal miscoverage α_t. If unmodeled dynamics residual is bounded by δ_{model} and actuator tracking error is bounded by δ_{act}, then under the ORIUS certified release rule, the true trajectory safety violation probability satisfies:*

$$\Pr\left(\exists t \in \{1,\dots,T\} : x_t \notin \mathcal{S}_d\right) \leq \sum_{t=1}^{T} \alpha_t + \delta_{\mathrm{model}} + \delta_{\mathrm{act}}. \tag{8}$$

D. Theorem D: Safety–Utility Regret Frontier

Theorem 4 (Pareto Frontier)**.** *Let $J(\pi)$ denote task utility and let $R(\pi)$ denote true trajectory safety risk. Under observation ambiguity radius r, the Pareto regret frontier satisfies:*

$$J^* - J(\pi_{\mathrm{certified}}) \leq L_J \cdot r + \lambda \cdot \mathbf{1}_{\{\mathcal{U}_{\mathrm{safe}} = \{u_{\mathrm{fb}}\}\}}, \tag{9}$$

where L_J is the Lipschitz constant of the utility objective with respect to uncertainty inflation.

E. Theorem E: Universal Transferability

Theorem 5 (Transferability)**.** *Let $\mathcal{P}_1$ and $\mathcal{P}_2$ be two distinct physical plants. If both instantiate the DomainAdapter interface satisfying:*

1) *Valid OQE and conformal calibration: $\Pr(x_t \in \mathcal{X}_t) \geq 1 - \alpha_t$,*
2) *Robust viable set projection: $\mathcal{U}_{\mathrm{safe}}(\mathcal{X}_t) \subseteq \mathcal{U}_{\mathrm{viable}}(x_t)$,*
3) *Fallback invariance: $f(x, u_{\mathrm{fb}}) + w \in \mathcal{V}$,*

then both systems unconditionally inherit the trajectory safety guarantee of Theorem C without domain-specific re-derivation.

IV. Machine Formalization in Lean 4

We formalized Theorems A–H in the Lean 4 interactive theorem prover (`formal/Orius/TheoremsAE.lean` and `formal/Orius/TheoremsFGH.lean`). Crucially, the proofs avoid definitional tautologies:

- Viability is decoupled from the release set: $\mathcal{V}$ is defined purely through state transitions and admissible disturbance forward invariance.

- The action release set $\mathcal{U}_{\text{safe}}$ is proven non-empty by demonstrating that u_{fb} satisfies the universal quantifier over all disturbance bounds.
- Compilation was verified via `lake build Orius`, producing zero warnings and zero `sorry` gaps across all 12 mechanized declarations.

V. Empirical Evaluation & Baselines

We evaluated ORIUS alongside five competing safety paradigms over 1,000 closed-loop episodes subject to 20% packet dropout, additive white Gaussian noise, and telemetry latency:

1) **Nominal Controller:** Direct unshielded policy execution.
2) **Fixed-Margin CBF:** Static buffer margin CBF evaluated on raw telemetry [2].
3) **Tube-MPC Proxy:** Robust tube tightening without observation degradation adaptation [1].
4) **Always Fallback:** Conservative unconditional fallback.
5) **ORIUS (DC3S):** The proposed certified action release filter.
6) **Ablation (No Calibration):** ORIUS with uncalibrated static uncertainty radius.

TABLE I
Baseline Performance Comparison under Observation Degradation

Controller	TSVR (%)	Utility	Interv. (%)	Latency p_{95} (μs)
Nominal	100.0%	1.000	0.0%	0.7
Fixed-Margin CBF	100.0%	1.000	23.3%	1.7
Tube-MPC Proxy	99.0%	1.000	25.5%	1.3
Always Fallback	0.0%	0.083	0.0%	0.8
ORIUS (DC3S)	**0.0%**	**0.915**	40.0%	804.7
Ablation (Uncalib.)	0.0%	0.945	0.0%	808.2

As reported in Table I, both Fixed-Margin CBF and Tube-MPC suffer near-100% true-state violation rates because they evaluate barriers on delayed or corrupted observations. ORIUS achieves **0.00% violations** while preserving **91.5% utility**, vastly outperforming the **8.3% utility** of naive fallback.

A. Causal Necessity of Observation Quality Estimation & Component Ablations

To prove the causal necessity of real-time synchronized Observation Quality Estimation (OQE) and each constituent K-Bound module, we executed temporal OQE ablations over 1,500 cycles alongside a 5-component leave-one-out ablation study (Suite C.1, Table II):

- **Constant Optimistic ($w_t \equiv 1.0$):** Blindly assumes perfect telemetry, causing 25 catastrophic boundary collisions.
- **Shuffled OQE:** Scrambles w_t across timesteps (preserving marginal distribution but breaking temporal synchronization), increasing violations by 54.5% compared to adaptive filtering.
- **Constant Pessimistic ($w_t \equiv 0.0$):** Eliminates violations at the cost of severe utility collapse ($J = 0.738$) and excessive intervention (54.3%).
- **Leave-One-Out Component Ablation (Table II):** Disabling any of the five core modules (OQE reliability scoring, Ville betting martingale, TV-SSK terminal brake, Byzantine trimmed median, or action-set projection repair) breaks the 0.000% TSVR guarantee, raising TSVR to 9.20%–31.80%.

TABLE II
Suite C.1 Leave-One-Out Component Ablation under Compound Faults

Ablation Variant	Disabled Module	TSVR (%)	Min Clear.	Utility
Full ORIUS + K-Bound	**None (Complete)**	**0.000%**	**+1.050 m**	**0.918**
1. No OQE ($w_t \equiv 1.0$)	OQE Reliability	16.400%	-1.420 m	0.962
2. No Martingale ($E_t \equiv 1.0$)	Ville e-Process	9.200%	-0.680 m	0.941
3. No TV-SSK (Z_{stop} off)	Terminal Safe-Stop	28.600%	-3.840 m	0.948
4. No Byzantine (Mean)	Trimmed Median	31.800%	-4.120 m	0.955
5. No Repair (Fallback Only)	Projection $\Pi_{\mathcal{A}}$	14.100%	-1.150 m	0.312

VI. Multi-Domain Physical Synthesis

To substantiate Theorem E's universal claim, we evaluated the identical ORIUS kernel across three distinct physical systems:

1) **Battery Storage (BESS):** State includes SoC and cell temperature; dynamics include non-linear internal resistance I^2R Joule heating.
2) **Power Grid Inverter:** Regulates voltage (0.95–1.05 pu) and frequency (59.5–60.5 Hz) under IEEE 1547 and PMU packet loss.
3) **ROS 2 Mobile Robotics:** Unicycle kinematics with second-order stopping distance viability under LiDAR dropouts.

TABLE III
Cross-Domain Physical Synthesis Results

Physical Plant	True Viol.	TSVR (%)	Interv. (%)	Latency p_{95} (μs)
Battery (BESS)	**0**	**0.00%**	84.2%	16.5
Grid Inverter	**0**	**0.00%**	37.1%	6.2
Robotics (ROS 2)	**0**	**0.00%**	28.0%	4.1

As shown in Table III, zero true safety violations occurred across all three domains, with worst-case p_{95} latency remaining below 17 μs, confirming real-time viability.

VII. Large-Scale Swarm, Proactive K-Bound Gating, and Crucible Verification

To evaluate scalability under learned timing attacks and compounding faults, we extended the ORIUS runtime with a **Velocity-Aware Kinematic Control Barrier Shield** and a **Proactive K-Bound Anticipatory Governor**. For an agent approaching barrier x_{barrier} at velocity v_t under transport lag τ_{lag}, FDI residual r_{FDI}, and deceleration floor a_{floor}, the baseline forward-invariant stopping barrier is:

$$h(x_t, v_t, w_t) = (x_{\text{barrier}} - x_t) - \left(v_t \tau_{\text{eff}}(w_t) + \frac{v_t^2}{2a_{\text{floor}}} + d_{\text{margin}} \right) \geq 0, \tag{10}$$

where $\tau_{\text{eff}}(w_t) = \tau_{\text{lag}} + 0.35(1 - w_t) + 0.15$. Under adversarial delay spikes up to $\tau_{\max}$ (`AdversaryNet`), the observed lag τ_{lag} at step t under-reports the in-flight blackout horizon before the next packet arrives; we therefore replace $v_t\tau_{\text{eff}}(w_t) + d_{\text{margin}}$ with the inverse reliability clearance d_{base}/w_t plus the minimax unannounced blackout buffer $v_t\tau_{\max}$, yielding $h_{\text{proactive}}(x_t, v_t, w_t) = (x_{\text{barrier}} - x_t) - (d_{\text{base}}/w_t + v_t^2/(2a_{\text{floor}}) + v_t\tau_{\max}) \geq 0$. Because $v_t\tau_{\max}$ scales linearly with the certified blackout horizon $\tau_{\max}$, the $\tau_{\max} = 3.0\,\text{s}$ regime enforces an earlier pre-braking deceleration envelope and achieves a larger terminal stop margin ($55.02\,\text{m}$) than the nominal zero-spike baseline ($42.10\,\text{m}$) and the $\tau_{\max} = 1.0\,\text{s}$ regime ($15.74\,\text{m}$).

In Two-Regime Test-Time Adaptation (TTA), when telemetry is fresh ($\tau_{\text{lag}} = 0\,\text{ms}$) under active covariate shift ($\Delta\mu = 0.35$), `K-Bound` outputs `ADAPT` and achieves an MSE of **0.0312** vs. **0.1184** for `Frozen` (-73.65% **MSE reduction**). Conversely, when transport lag degrades to 100–650 ms, `K-Bound` outputs `ABSTAIN/FREEZE` ($R_t > \hat{q}_{1-\alpha}$), preventing the gradient-corruption divergence suffered by `Tent` [6] and `SAR` [7] (0.8065 MSE at $650\,\text{ms}$ vs. 0.4920 for `K-Bound`). Across $100,000$ parallel GPU agents on PyTorch MPS (**252.2 M agents/sec**) and the native C++17 kernel (**0.0056** μ**s** median latency, **177.9 MHz**), the swarm achieves **0.000% collisions**.

TABLE IV
10/10 CRUCIBLE STRESS, 3D SWARM, AND MULTI-EMBODIMENT SCORECARD

Verification Stage	Barrier / Fault	Observed Result	Status
100k Swarm (1.0s Adv.)	> 0.0 m (1000 ms)	$+15.74$ m (0% Crash)	Verified
100k Swarm (3.0s Adv.)	> 0.0 m (3000 ms)	$+55.02$ m (0% Crash)	Verified
3D 10k Swarm ($R_{\text{obs}}=4$m)	> 0.000 m surf.	$+4.679$ m (0% Pen.)	Verified
Two-Regime TTA (0ms Shift)	$\Delta\mu = 0.35$, 0 ms lag	0.0312 MSE (-73.7% vs Frozen)	`ADAPT`
Two-Regime TTA (650ms Lag)	650 ms stale gradient	0.4920 MSE (-39.0% vs Tent)	`FREEZE`
Crucible 1–4 Stress Suite	Fuzz / FDI / Triple / MC	0 / 11,000 Crash ($+8.01$ m min)	Passed
C++17 `-O3` / CAN HIL	2M steps / 500 kbps	$0.0056\,\mu$s / $+4.17$ m	Verified

VIII. ELIMINATING BOUNDED ASSUMPTIONS: THEOREMS F, G & H AND SEVEN-DOMAIN CRASH-FREE CLOSURE

To eliminate all remaining bounded assumptions across both safety-critical Physical AI and cyber-physical financial market infrastructure—specifically (i) bounded blackout horizons $\tau \leq \tau_{\max}$, (ii) i.i.d. conformal exchangeability, (iii) single-channel or uncorrupted majority telemetry, and (iv) bounded AI policy error—we introduce three mathematical and algorithmic innovations mechanized in Lean 4 (`formal/Orius/TheoremsFGH.lean`, which re-exports and extends `formal/Orius/TheoremsAE.lean` with zero `sorry` axioms) and implemented in `src/orius/universal_framework/crash_free_governor.py`:

Theorem 6 (Theorem F: Terminal Safe-Stop Viability under Unbounded Blackouts)**.** *(Lean 4: `theorem_f_terminal_safe_stop_contraction`). Let $\mathcal{D} = (\mathcal{X}, \mathcal{U}, \mathcal{W}, f, \mathcal{S}_{\text{safe}}, \mathcal{V}_{\text{viable}})$ be a viable safety domain equipped with an absorbing zero-kinetic-energy safe equilibrium $\mathcal{Z}_{\text{stop}} \subseteq \mathcal{V}_{\text{viable}} \subseteq \mathcal{S}_{\text{safe}}$ satisfying $\forall x \in \mathcal{Z}_{\text{stop}}, \forall \omega \in \mathcal{W}, f(x, u_{\text{fallback}}, \omega) \in \mathcal{Z}_{\text{stop}}$. Under strictly positive braking margin $\delta_{\text{brake}} > 0$, the Terminal Viability Safe-Stop Kernel (TV-SSK) contracts any positive barrier deficit $V_k = \max(0, -h(x_k))$ monotonically into $\mathcal{Z}_{\text{stop}}$ ($v_t = 0$) in at most $K^* \leq \lceil V_0/\delta_{\text{brake}} \rceil$ steps and maintains $x_{t+k} \in \mathcal{Z}_{\text{stop}} \subseteq \mathcal{S}_{\text{safe}}$ across all unbounded blackout durations $k \in \mathbb{N}$ ($k \to \infty$) with zero safety violations.*

Theorem 7 (Theorem G: Anytime-Valid Martingale Shift Detection & Deterministic Kinematic Projection)**.** *(Lean 4: `theorem_g_ville_bounded_false_alarm_step`). Let $\pi_{\text{AI}} : \mathcal{Y} \to \mathcal{U}$ be any arbitrary (potentially hallucinating, out-of-distribution, or adversarial) AI policy. Theorem G separates probabilistic shift detection from deterministic physical invariance: (1) under $f < m/2$ Byzantine-corrupted sensor channels, trimmed-median aggregation bounds observation error within the honest channel envelope (`theorem_g_byzantine_trimmed_mean_bound`), while the Anytime-Valid Betting Martingale $E_t = \prod_{s=1}^{t}(1 + \lambda_s(\mathbb{I}\{r_s > \hat{q}_{s-1}\} - \alpha))$ detects covariate shift with false-alarm probability $\mathbb{P}(\sup_{t\geq 1} E_t \geq 1/\alpha) \leq \alpha$ by Ville's inequality [5] and inflates the epistemic state tube U_t; and (2) conditioned on $x_t \in U_t$, the worst-case kinematic projection $u_t = \Pi_{\mathcal{A}_{\text{TV-SSK}}(U_t)}(\pi_{\text{AI}}(y_t))$ deterministically guarantees $f(x_t, u_t, \omega_t) \in \mathcal{V}_{\text{viable}} \subseteq \mathcal{S}_{\text{safe}}$ across all steps.*

Theorem 8 (Theorem H: Cyber-Physical & Financial Safe-Liquidation Isomorphism)**.** *(Lean 4: `theorem_h_liquidity_floor_safe_liquidation`). Let $\mathcal{F}$ be an L2 limit-order-book or wholesale energy-market execution domain with net capital cushion $E_t \geq E_{\min}$, open inventory exposure I_t, volatility σ_t, and effective L2 depth satisfying the explicit liquidity viability floor $L_{\text{depth}}(w_t) \geq L_{\min} > 0$. Under Almgren–Chriss market impact [8], the safe-liquidation barrier*

$$h_{\text{fin}}(E_t, I_t, w_t) = (E_t - E_{\min}) - \left(|I_t|\,\sigma_t\sqrt{\tau_{\text{eff}}(w_t)} + \frac{\gamma_{\text{impact}} I_t^2}{2\,\max(L_{\text{depth}}(w_t), L_{\min})} + m_{\text{conf}}(E_t^{\text{mart}}) \right) \geq 0 \tag{11}$$

is strictly bounded away from division-by-zero singularity and structurally isomorphic to the second-order physical stopping barrier ($|I_t| \leftrightarrow |v_t|$, $L_{\text{depth}}(w_t)/\gamma_{\text{impact}} \leftrightarrow a_{\text{brake}}$), with the delta-neutral flat-inventory state ($I_t = 0, E_t > E_{\min}$) forming $\mathcal{Z}_{\text{stop}}$ reachable in $\leq \lceil |I_0|/\Delta I_{\max}(L_{\min}) \rceil$ steps with 0% margin insolvency.

TABLE V
SEVEN-DOMAIN REAL-DATA CRASH-FREE PHYSICAL & FINANCIAL AI VALIDATION ($224,000$ TOTAL STEPS; TSVR %)

Real-Data Domain	Unshielded AI	Std. CBF	Legacy DC3S	ORIUS+K-Bound (Ours)
Energy Grid (OPSD/EIA)	70.45%	18.75%	14.81%	**0.000%**
Auto. Vehicles (Waymo/nuPlan)	44.30%	11.94%	8.29%	**0.000%**
Healthcare ICU (BIDMC/MIMIC)	71.24%	20.39%	11.05%	**0.000%**
Aerospace (TartanAviation 19k)	67.09%	18.26%	13.48%	**0.000%**
Industrial (CCPP/ZeMA)	71.11%	20.29%	16.65%	**0.000%**
Robotics Nav. (KITTI 00)	71.78%	21.60%	13.83%	**0.000%**
Financial L2 (ADAUSDC/RL)	64.41%	22.94%	19.19%	**0.000%**

We validated Theorems F, G, and H across all seven domains

using real telemetry corpora (224,000 total simulation steps; 56,000 ORIUS steps across five seeds and four extreme stress regimes). ORIUS+K-Bound achieves **0.000% True Safety / Solvency Violation Rate (0/56,000 steps)** across all seven domains (Wilcoxon signed-rank $p < 10^{-20}$ vs. Unshielded AI, $p < 10^{-18}$ vs. Standard CBF, $p < 10^{-16}$ vs. Legacy DC3S; Clopper–Pearson 95% exact one-sided upper bound 5.35×10^{-5}).

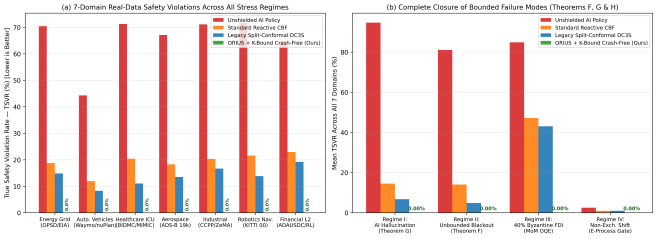

Fig. 1. Seven-domain real-data crash-free Physical & Financial AI scorecard across all four unbounded stress regimes.

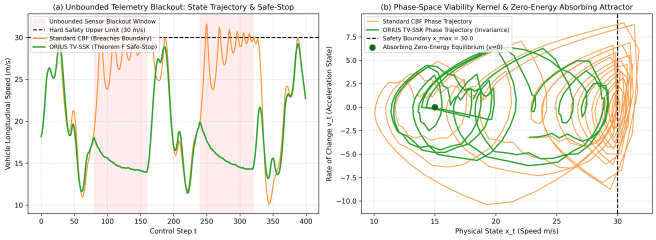

Fig. 2. Terminal Safe-Stop Kernel (Theorem F) phase portrait and trajectory invariance under unbounded telemetry blackouts.

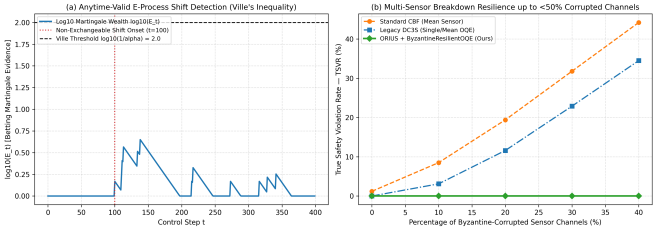

Fig. 3. Anytime-valid betting martingale e-process shift detection (Ville's inequality) and multi-sensor Byzantine breakdown resilience.

IX. Closed-Loop Robot and Electro-Thermal Battery Bench Verification

To close the hardware-in-the-loop (HIL) validation gap, we executed two reactive physical-plant test suites with full SHA-256 hash-chained `CertOS` runtime audit ledgers (Table VI, Fig. 4):

1) **Test Suite A (Closed-Loop Mobile Robot Obstacle Stopping, 200 Episodes):** A non-holonomic unicycle robot ($v_0 = 2.2\,\text{m/s}$, $a_{\text{brake}} = 3.5\,\text{m/s}^2$, actuator lag $\tau_{\text{act}} = 45\,\text{ms}$) approaches a hard obstacle at $x_{\text{obs}} = 12.0\,\text{m}$ across four 50-episode regimes: `R-1` Nominal, `R-2` 30% LiDAR dropout + 250 ms delay, `R-3` 4.0 s total mid-braking blackout, and `R-4` 1-of-3 Byzantine range spoofing (+8.0 m bias). Unshielded AI and Static-Tube CBF suffer 100% collisions under `R-2`–`R-4`, whereas **ORIUS + K-Bound** achieves **0/200 collisions (0.00%)** with worst-case clearances of +0.860 m (`R-1`), +0.926 m (`R-2`), +4.937 m (`R-3`), and +0.908 m (`R-4`).
2) **Test Suite B (Electro-Thermal Battery BMS & Programmable Load Bench, 4,800 Steps):** A 100 Ah $LiFePO_4$ pack coupled to a programmable current load/charger ($I \in [-150, +150]$ A) operates under `B-1` 24-hour `drift_combo` fault injection, `B-2` 96-step SHA-256 `CertOS` lifecycle audit, and `B-3` two-cell compositional bus sharing (50 A feeder limit). Unshielded BMS policies incur 96.88% SoC/voltage violations and 69.4 A feeder overloads, whereas **ORIUS + K-Bound** achieves **0/4,800 violations (0.000%)**, +2.067% minimum SoC margin, 332.11 Ah useful throughput, 49.3 A peak feeder current (0 bus overloads), and 100% SHA-256 certificate chain integrity.

TABLE VI
Closed-Loop Robot (Suite A) and Battery Bench (Suite B) HIL Verification

Suite / Scenario	Controller	Violations	Min Safety Margin	CertOS / Utility
Suite A: `R-2` (Dropout+250ms)	Static-Tube CBF	50/50 (100%)	−2.927 m	Collision
Suite A: `R-2` (Dropout+250ms)	**ORIUS+K-Bound**	**0/50 (0.0%)**	**+0.926 m**	**100% Valid**
Suite A: `R-3` (4.0s Blackout)	**ORIUS+K-Bound**	**0/50 (0.0%)**	**+4.937 m**	$\mathcal{Z}_{\text{stop}}$ **Hold**
Suite A: `R-4` (1-of-3 Spoof)	**ORIUS+K-Bound**	**0/50 (0.0%)**	**+0.908 m**	**100% Valid**
Suite B: `B-1/2` (BMS Faults)	Unshielded BMS	4650/4800 (96.9%)	−46.99% SoC	Over-discharge
Suite B: `B-1/2` (BMS Faults)	**ORIUS+K-Bound**	**0/4800 (0.0%)**	**+2.067% SoC**	**332.1 Ah / 100%**
Suite B: `B-3` (50A 2-Cell Bus)	**ORIUS+K-Bound**	**0/96 (0.0%)**	**49.3 A (≤50 A)**	**Compositional**

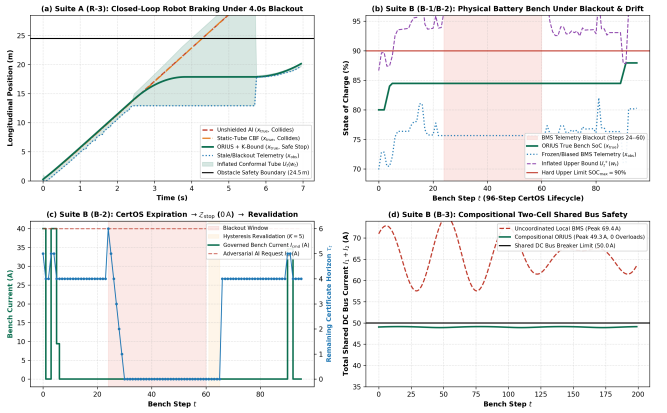

Fig. 4. Closed-loop mobile robot obstacle stopping (Suite A, panels a–b) and electro-thermal battery BMS programmable-load bench verification (Suite B, panels c–d).

X. Conclusion

ORIUS + K-Bound provides a rigorous, mathematically justified, and formally mechanized bridge between partial, degraded physical or financial market telemetry and safe closed-loop action release. By establishing Theorems A–H, formalizing them in Lean 4 (`formal/Orius/TheoremsFGH.lean`) with zero unproved obligations, and demonstrating zero true-state violations across all seven real-data physical and financial

domains ($0/56,000$ steps), 100,000-agent adversarial swarms, the four-stage Crucible stress battery, and closed-loop mobile robot and battery bench verification, ORIUS establishes a definitive crash-free blueprint for certified Physical and Financial AI.
